INTRODUCTION

Despite adequate lowering of body temperature and intensive care, the mortality is as high as 10%-15% in patients with heatstroke. Heatstroke often leads to multiple organ dysfunction syndrome (MODS) with a death rate of 40% or a neurological morbidity of 30%.[1-3] These high rates in patients with heatstroke are largely due to the progression of heat stress to MODS, resulting in no specific treatment available.

BACKGROUND: Heatstroke often leads to multiple organ dysfunction syndrome (MODS) with a death rate of 40% or a neurological morbidity of 30%. These high rates in patients with heatstroke are largely due to the progression of heat stress to MODS, resulting in no specific treatment available. This study aimed to develop a mouse model of heat stress and determine the pathological changes in the lung and brain during heat stress and cooling treatment.

METHODS: A mouse model of heat stress was established in a pre-warmed incubator set at 35.5 ± 0.5°C and with a relative humidity of 60% ± 5%. Rectal temperature was monitored, and at a temperature of 39 °C, 40 °C, 41 °C, or 42 °C, the mice were sacrificed. The remaining animals were removed from the incubator and cooled at an ambient temperature of 25 ± 0.5 °C and a humidity of 35% ± 5% for 12 or 24 hours at a temperature of 41 °C or for 6 hours at a temperature of 42 °C. The control mice were sham-heated at a temperature of 25 ± 0.5 °C and a humidity of 35% ± 5%. The lungs and brains of all animals were isolated. Hematoxylin and eosin staining and light microscopy were performed to detect pathological changes.

RESULTS: All mice demonstrated a uniform response to heat stress. A low degree of heat stress induced marked pathological changes of the lungs. With the rise of the temperature to 42°C, progressively greater damage to the lungs with further congestion of the lung matrix, asystomatic hemorrhage of alveolar space, abscission of alveolar epithelial cells, and disappearance of pulmonary alveolus tissue structure were detected. However, absorption of congestion and hemorrhage as well as recovery of pulmonary alveolus tissue structure was observed following cooling treatment at an ambient temperature. With a low degree of heat stress, the brain only showed moderate edema. Neuronal denaturation and necrosis were detected at a temperature of 42°C. Interestingly, the lesions in the brain were further aggravated at 42 °C regardless of cooling treatment, but recovery was observed after cooling treatment at 41 °C.

CONCLUSIONS: The pathological changes of the lungs and brain of mice showed distinctive lesions following heat stress and cooling treatment, and they were correlated with the time and duration of cooling treatment. The results of this study are helpful for further study of the mechanisms linking heatstroke.

specific treatment available.\textsuperscript{[4,5]}

Tissue damage is a common manifestation of heatstroke syndrome. Its complications include acute respiratory distress syndrome (ARDS), cerebral edema, disseminated intravascular coagulation (DIC), shock, rhabdomyolysis, renal failure, and hepatic dysfunction.\textsuperscript{[6,7]} The histopathology of injured tissue could reflect a common manifestation of MODS. To observe the pathological changes at the tissue level, we established a mouse heatstroke model, and cooling treatment was also applied to mimic clinical therapy. As clinical manifestations, pathological changes of the lungs and brain were assessed during heat stress and cooling recovery. The findings of this study help to investigate the mechanisms underlying heatstroke and MODS.

\section*{METHODS}

\subsection*{Animals}

Pathogen-free, 6-to 8-week-old male BALB/c mice were housed in barrier cages under controlled environmental conditions (35\% ± 5\% humidity at 25 °C) in the Experimental Animal Center of Southern Medical University, Guangzhou, China. The mice had free access to standard laboratory chow and water. All procedures dealing with the animals in this study were approved by the Animal Care and Use Committee of Southern Medical University before the experiment and were conducted under the Guidelines for Animal Care of Southern Medical University.

\subsection*{Heat stress protocol and cooling treatment}

The mice were fasted 12 hours before the experiment but allowed to have water and libitum. After stabilization for 20 hours at an ambient temperature of 25 ± 0.5 °C with a humidity of 35\% ± 5\%, 48 mice were divided into two groups: control group (n = 6) and heat stress (HS) group (n = 42). The mice of the HS group were placed in a prewarmed incubator at 35.5 ± 0.5 °C and a relative humidity of 60\% ± 5\% and a temperature of 39 °C followed by a decrease to 38 °C. After a slow rise over 3 hours, the temperature reached 42 °C. The temperature of the sham-heated animals didn't significantly change during the experiment. The mice at 42 °C were dead, because the temperature further increased to 43 °C in an incubator or at 6 hours after cooling treatment. Mice in the other groups survived for more than 24 hours.

\subsection*{Histopathological analysis}

The mice were anesthetized by intraperitoneal injection of urethane. The samples of the lungs and brains were excised, sectioned transversely or longitudinally, and fixed in 10\% neutral-buffered formalin. The sections were then embedded in paraffin and stained with hematoxylin and eosin for microscopic evaluation at a magnification of × 200. The extent of tissue injury was evaluated by two certified pathologists who knew nothing about the nature of the groups being assessed.

\section*{RESULTS}

\subsection*{Thermal responses of mice to heat stress and cooling treatment}

Thermal responses of mice during heat stress have been reported previously,\textsuperscript{[8]} i.e. the temperature reached 39 °C followed by a decrease to 38 °C. After a slow rise over 3 hours, the temperature reached 42 °C. The temperature of the sham-heated animals didn't significantly change during the experiment. The mice at 42 °C were dead, because the temperature further increased to 43 °C in an incubator or at 6 hours after cooling treatment. Mice in the other groups survived for more than 24 hours.

\subsection*{Tissue histopathology}

Histopathological investigation was performed and representative photomicrographs of the lungs and brains were taken (Figures 1 and 2).

\subsection*{Lungs}

No significant abnormalities were detected in the lungs of control mice (Figure 1A). Pathological changes were observed at 39 °C, characterized by angioatelectasis, congestion, and thickening of the lung matrix (Figure 1B). Progressively greater damage to the lungs with further congestion of the lung matrix, hemorrhage of the alveolar space, abscission of alveolar epithelial cells, and disappearance of pulmonary alveolus tissue structure were detected with the rise of a temperature to 42 °C (Figure 1C–E). However, absorption of congestion and hemorrhage as well as recovery of pulmonary alveolar tissue structure was observed for a long time after cooling treatment (Figure 1F–H).

\subsection*{Brain}

No significant abnormalities were detected in the brains of control mice (Figure 2A). At a low temperature of 39 °C or 40 °C, the brain only showed moderate edema, characterized by vacant space surrounding the neurons.
and capillaries (Figure 2 B and C). Neuronal denaturation and necrosis were detected when the temperature reached 41 °C, and they became more obvious at 42 °C (Figure 2 D–E). Interestingly, brain lesions were further aggravated with gliocyte disaggregation and more obvious edema and neuron necrosis after the temperature reached 41 °C or, especially, 42 °C, even after cooling treatment at ambient temperature (Figure 2 F–H).

DISCUSSION

Heatstroke is a life-threatening illness characterized by a rapidly increasing core body temperature (temperature >40 °C) and central nervous system abnormalities such as delirium, convulsions, and coma after exposure to a high ambient temperature (classical or nonexertional heatstroke) or strenuous exercise (exertional heatstroke). Current reports suggest that pathophysiological responses to heatstroke may not be due to the immediate effects of heat exposure but to a systemic inflammatory response syndrome (SIRS) induced by thermal injury. The high mortality observed after heatstroke is thought to be secondary to the occurrence of multi-organ dysfunction.\textsuperscript{9,11} Frequently encountered complications include ARDS, cerebral edema, seizures, DIC, shock, rhabdomyolysis, renal failure, and
hepatic dysfunction.\textsuperscript{12,13}

Leon et al\textsuperscript{9} observed lesions in the duodenum, spleen, and kidney in mice after heat strain, but there were no significant abnormalities in the liver, brain, heart, lung, or large intestine. In heat stress in baboons, Bouchama et al\textsuperscript{14} found that tissue damage of varying degree was present in the liver, brain, and gut. These studies only detected pathological changes at a single time point in heatstroke animals. In our study we determined pathological changes after heatstroke and cooling recovery.

To investigate predictors of MODS in patients with heatstroke, Varghese et al\textsuperscript{15} found that respiratory failure (85.7\%) was common, and more than three quarters of such patients required mechanical ventilation. Kibayashir et al\textsuperscript{16} found pulmonary edema and acute microvascular lung injury after heat stress at a single time point. In our study, obvious pathological changes and progressively greater damage to the lungs during heat stress, absorption of congestion and hemorrhage and recovery of pulmonary alveolus tissue structure were also found for a prolonged time after passive cooling at ambient temperature. These changes were consistent with the clinical manifestations of patients with heatstroke, whose pulmonary function was usually impaired but recovered quickly.

According to the definition of heatstroke, the pathological changes of the central nervous system (CNS) are essential to the understanding of its pathophysiological mechanisms. However, there is little information about the occurrence of brain lesions. In our study, injury to the brain appeared even at 39 °C, and this was further aggravated with a rise of the temperature regardless of cooling treatment. The findings were consistent with the clinical manifestations of heatstroke patients who present with CNS dysfunction and neurological morbidity.

In conclusion, our study provides evidence for lesions in the lungs and brain after heat stress, including those after a cooling recovery. These changes are correlated with the timing and duration of cooling treatment, and help to investigate the relationship between heatstroke and MODS. The limitations of this study include no data obtained from a model of exertional heat stroke, nor determination of the relationship between organ function and the observed tissue damage, which may provide substantial information about the pathophysiology of heatstroke.
