INTRODUCTION
Use of caffeinated energy drinks is a growing health concern worldwide. There are growing concerns of adverse effects including addiction, neuropsychiatric, cardiac and metabolic adverse effects. We report a young male patient suffering from fatal myocardial infarction due to overdose of energy drink combined with ecstasy. To our knowledge, this is the first report of fatal myocardial infarction that may be related to energy drinks.

Case presentation
A 24-year-old Caucasian man presented to the Emergency Department with a one-hour history of crushing chest pain, nausea, and vomiting. He was brought from a night club, where he works as a doorman. He reported consuming about 20 cans of energy drink (XL) over the previous night, but denied taking any drugs or drinking any alcohol.

His medical history included overweight (BMI of about 40), and a mild hypertension for which he denied taking medications. There was no family history of ischemic heart disease.

On arrival, he was anxious, sweating, and tachycardic (110 beats/minute), with blood pressure 90/60 mmHg. Heart sounds were normal on auscultation, and respiratory examination revealed slight basal rales, with no jugular vein distension.

Electrocardiogram (ECG) on admission (Figure 1) showed widespread ST segment elevation confirming acute myocardial infarction. He was given aspirin, oxygen, and morphine, and was preceded to primary percutaneous intervention (PCI). While waiting for the Cath-Lab team, the patient developed a wide complex tachycardia (Figure 2), which was resistant for administration of DC shocks and a bolus of amiodarone. His level of consciousness deteriorated, and he was then intubated. His cardiac rhythm further deteriorated to ventricular fibrillation (Figure 3). Resuscitation according to ACLS protocols was carried out, while a
cardiologist inserting a pacemaker. Time for pacemaker placement was 15 minutes. In spite of all the resuscitative efforts, the medical team in place had to announce the patient's death after more than half an hour resuscitation, and after a bedside echocardiogram failed to demonstrate any spontaneous cardiac activity.

Because of the rare and dramatic presentation, atypical in young men, a urine sample was sent for toxic screening, and it returned out to be positive for urine specimen showing the presence of 3, 4-methylenedioxymethamphetamine (MDMA). The patient's family refused the execution of post mortem investigation.

**DISCUSSION**

The recreational use of commercial energy drinks is a growing habit in most of the world, and there are reports about their adverse effects.\[1-4\] These drinks contain, among other ingredients, large amounts of caffeine. Though these drinks contain many other ingredients in addition to caffeine, there is little evidence they bare any hazards.\[5\] Caffeine in high doses is well related to various adverse effects, and though it has a wide therapeutic index, there are many reports of serious toxicities, even death.\[6\] One study\[7\] found that one hour after consumption of a caffeine drink containing caffeine (80

mg), taurine (1000 mg), and glucuronolactone (600 mg), there are objective cardiovascular changes characterized by an increase in blood pressure and an increase in platelet aggregation.\textsuperscript{[17]} Physiologic studies\textsuperscript{[8–9]} indicate a reduction of myocardial reserve by caffeine, providing a biological plausibility for the sudden deaths reported in the literature. There are several series in the literature describing the direct link between heavy caffeine intake, mostly in coffee, and myocardial infarctions.\textsuperscript{[10–11]}

Earliest symptoms of acute caffeine poisoning are usually anorexia, tremor, and restlessness, followed by nausea, vomiting, tachycardia, and agitation. With serious intoxication, delirium, seizures, supraventricular and ventricular tachyarrhythmias, hypokalemia, and hyperglycemia may occur. Hypotension is caused by excessive beta-2-mediated vasodilatation and is characterized by a low diastolic pressure and a wide pulse pressure. The lethal oral caffeine dose is considered to be 10 grams. One can of the commercial energy drinks contains 40–200 milligrams of caffeine (about equal to one cup of coffee). The recommended daily caffeine dose for an adult is a maximum of 400 mg.\textsuperscript{[12]} Relying on this figure, the patient in our case drank in a few hours 5 times more than the safe daily dose.

MDMA (3, 4-methylenedioxymethamphetamine), the other drug of abuse ingested by the patient, is a synthetic phenyl ethylamine derivative structurally related to both amphetamines and mescaline. It is commonly known by the street name "ecstasy". MDMA is best known for its psychedelic properties and unique effects on mood and intimacy. The increase in popularity of MDMA has been accompanied by an increase in reports of serious complications and death related to its use.\textsuperscript{[13–16]} There are reports on morbidity and mortality due to cardiac effects of MDMA by coronary thrombosis and arrhythmia.\textsuperscript{[15–18]}

In conclusion, though the cardiac hazards of caffeine and MDMA are known, there are no descriptions of their combined effects so far. Moreover, there are no descriptions in the literature of cardiac mortality due to ingestion of energy drinks, though their use (or abuse) is a growing problem worldwide. This may be due to lack of awareness to this problem.
